**ABSTRACT:** The Rydberg radical  $\text{NH}_4$  and the double Rydberg anion (DRA)  $\text{NH}_4^-$  have long aroused researchers' interests due to their potential for exploring the reaction dynamics of the  $\text{H} + \text{NH}_3 \rightarrow \text{H}_2 + \text{NH}_2$  reaction, a prototypical penta-atomic system. In this study, we present high-resolution photodetachment spectroscopy of DRA  $\text{NH}_4^-$  and ion–molecule complex  $\text{H}^-(\text{NH}_3)$ . We observed multiple new photodetachment channels of DRA  $\text{NH}_4^-$ . The energy level of the excited state ( $3p\ ^2T_2$ ) of the Rydberg radical  $\text{NH}_4$  was determined to be  $15052(94)\text{ cm}^{-1}$ , in excellent agreement with the principal Schüler band ( $15061.61\text{ cm}^{-1}$ ). Additionally, we observed the tunneling dissociation of  $\text{NH}_4^-$  in a cryogenic ion trap with its dissociation lifetime determined to be  $19(2)\text{ ms}$ .

The concept of Rydberg molecules<sup>1</sup> was first introduced by Herzberg in 1981 through the emission spectra of the ammonium radicals  $\text{NH}_4$ ,<sup>2</sup> wherein Rydberg states exhibit stability while their ground states are unstable, resembling  $\text{H}_3$ .<sup>3</sup> Subsequently, a neutralized ion-beam experiment<sup>4</sup> suggested the presence of a small barrier on their ground-state potential energy surface (PES), which separates the  $T_d$  symmetry minimum from the dissociative channel, with an evaluated lifetime  $<1\ \mu\text{s}$ . Several theoretical studies<sup>5–7</sup> on  $\text{NH}_4$  also support this conclusion, suggesting that the fragile Rydberg species readily overcome the shallow barrier and then dissociate into reactive radicals (i.e.,  $\text{NH}_4 \rightarrow \text{H} + \text{NH}_3$ ). Recently, anion photoelectron-photofragment coincidence (PPC) experiments combined with quantum dynamics calculations on a global PES by Hu et al.<sup>8</sup> indicate the dissociation of the nascent Rydberg radical  $\text{NH}_4$  into  $\text{H}$  and  $\text{NH}_3$  with a barrier energy of  $0.329\text{ eV}$ , re-estimating this dissociation lifetime to be  $<100\text{ ns}$ .

While it is possible to probe the tunneling process of neutral metastable  $\text{NH}_4$  species via the photodetachment of the double Rydberg anion (DRA)  $\text{NH}_4^-$ , experimental observation of the dissociation of the DRA has not been reported.  $\text{NH}_4^-$  was the first observed DRA molecule by Bowen and co-workers,<sup>9–11</sup> comprising a closed-shell parent cation core  $\text{NH}_4^+$  and a pair of diffuse outer electrons. Both neutral  $\text{NH}_4$  and  $\text{NH}_4^-$  DRA possess tetrahedral geometries that resemble the corresponding cation cores  $\text{NH}_4^+$ . The Bowen group studied  $\text{NH}_4^-$  DRA using photoelectron spectroscopy, and they also observed a separated feature contributed by the ion–molecule complex  $\text{H}^-(\text{NH}_3)$  in the same energy spectrum. These two anionic isomers are distinguished on the energy spectrum by a sharp peak with a measured binding energy of  $0.48\text{ eV}$  and a

structureless broad peak at  $1.11\text{ eV}$ , respectively. The photodetachment of the two anionic isomers provides a unique approach to probe the reaction dynamics of the  $\text{H} + \text{NH}_3 \rightarrow \text{H}_2 + \text{NH}_2$  reaction, a prototypical penta-atomic system.<sup>12–14</sup> The latest measurements by the Continetti group reported  $1.12(7)\text{ eV}$  for  $\text{H}^-(\text{NH}_3)$  and  $0.48(6)\text{ eV}$  for  $\text{NH}_4^-$  based on the fast anion beam PPC spectrometer.<sup>8</sup> So far,  $\text{NH}_4^-$  DRA has never been produced alone and is always accompanied by its  $\text{H}^-(\text{NH}_3)$  isomer in the energy spectrum. On the theoretical side, high-level calculations have offered a solid complementary support for the identification of these anionic isomers.<sup>15–18</sup>  $\text{H}^-(\text{NH}_3)$  located at the global minimum and  $\text{NH}_4^-$  located at a local minimum on the PES. In the present work, we report the high-resolution photoelectron spectra of two anionic isomers and the observation of the tunneling dissociation of  $\text{NH}_4^-$  DRA in a cryogenic ion trap.

Another motivation of the present work is to observe the Schüler band of  $\text{NH}_4$  using high-resolution photodetachment spectroscopy at higher photon energy. In hollow-cathode discharges through  $\text{NH}_3$ , Schuster in 1872<sup>19</sup> and Schüler et al. in 1955<sup>20</sup> observed a number of emission bands. These diffuse bands remained a mystery for over a hundred years until the isotope studies conducted by Herzberg in 1981.<sup>2</sup> Initially, the two bands in the visible region were assigned to the ammonium radical  $\text{NH}_4$  by Herzberg,<sup>2,21</sup> analogous to the D

lines of the isoelectronic Na atom. However, precise assignments of the bands to the transitions of  $\text{NH}_4^-$  were challenging at that time. In 1986, Watson et al. argued that the previous identification by Herzberg was not definitive.<sup>22</sup> They reassigned the Schuster bands to the reaction gases  $\text{NH}_3$  and  $\text{ND}_3$ ,<sup>22</sup> and the Schüler bands to the transition  $^2\text{T}_2$  ( $3\text{p}$ )  $\rightarrow$   $^2\text{A}_1$  ( $3\text{s}$ ) of  $\text{NH}_4^-$  instead of the proposed  $^2\text{E}_1$  ( $3\text{d}$ )  $\rightarrow$   $^2\text{T}_2$  ( $3\text{p}$ ) assignment.<sup>23</sup> Theoretical calculations by Martin et al.<sup>24</sup> and Ortiz et al.<sup>25</sup> also supported their conclusions. Recently, the Continetti group<sup>26</sup> produced exotic neutral  $\text{NH}_4$  by the charge exchange neutralization of the ammonium cation  $\text{NH}_4^+$  and observed that the spacing between the assigned  $3\text{s}$  ( $\nu = 0$ ) peak and the highest-energy resolved feature ( $3\text{p}_{\text{max}}$ ) is 1.87 eV ( $\sim 15083\text{ cm}^{-1}$ ) in the kinetic-energy-release (KER) spectrum, closely matching the principal Schüler band ( $15061.61\text{ cm}^{-1}$ ).<sup>21</sup>

The experiments were conducted on our slow-electron velocity-map imaging apparatus equipped with a cryogenic ion trap (cryo-SEVI), with further details provided elsewhere.<sup>27,28</sup> In this study, both  $\text{NH}_4^-$  and  $\text{H}^-(\text{NH}_3)$  were generated by expanding a mixed gas of ammonia and helium through a pulsed valve fitted with a high-voltage electron-gun ion source.<sup>29</sup> The backing pressure was about  $5 \times 10^5\text{ Pa}$ . The produced anions were guided into a radiofrequency (rf) octupole ion trap<sup>30</sup> with the assistance of the rf hexapole guide. The temperature of the ion trap could be adjusted from 300 to 5 K as it is mounted on the cold head of a liquid helium chiller. The trapped anions were cooled by collisions with the buffer gas composed of 20%  $\text{H}_2$  and 80% He for a duration of 5–45 ms during the storage period. Subsequently, the anions can be extracted from the trap and mass-selected using time-of-flight (TOF).<sup>31</sup> In the photodetachment region, the selected  $\text{NH}_4^-$  or  $\text{H}^-(\text{NH}_3)$  anions were photodetached at various photon energies by using a tunable optical-parametric-oscillator (OPO) laser. The detached photoelectrons were analyzed via a velocity-map imaging (VMI) spectrometer<sup>32,33</sup> and their distributions were reconstructed from the projected photoelectron image utilizing the maximum entropy velocity Legendre reconstruction (MEVELER) method.<sup>34</sup>

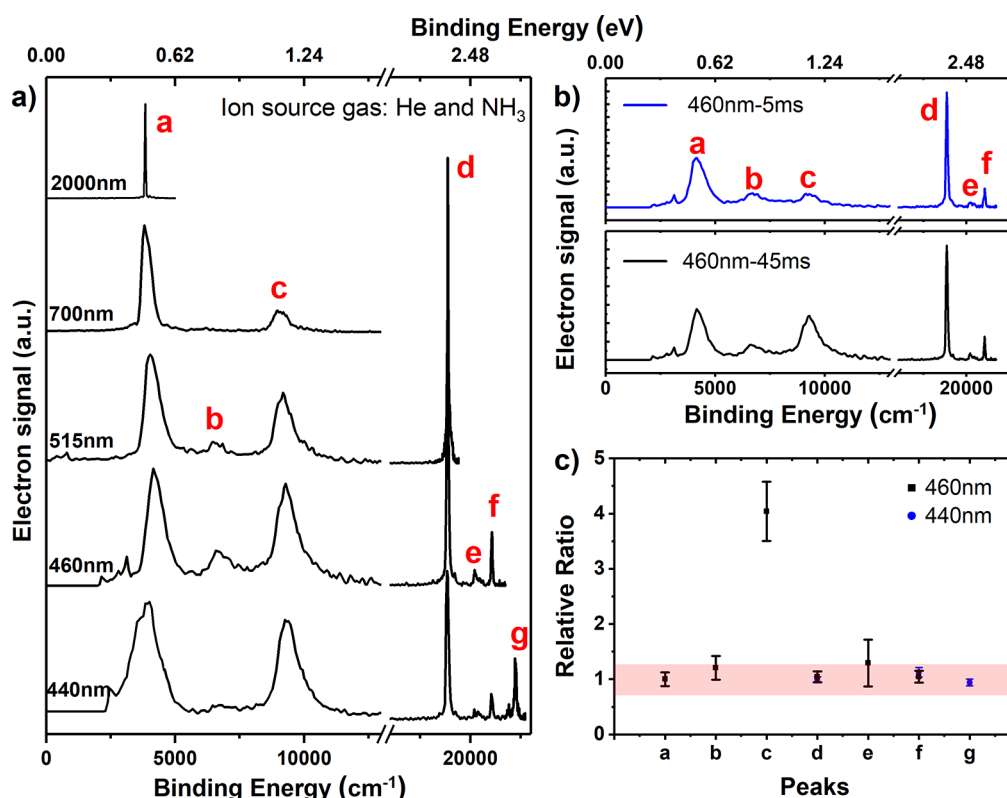

Figure 1 displays the full photoelectron energy spectrum of anionic isomers  $\text{NH}_4^-$  and  $\text{H}^-(\text{NH}_3)$  acquired by using the cryo-SEVI method. The ion-source gas is a mixture of  $\text{NH}_3$  and He in a ratio of  $\sim 1:2$ . Peak a is attributed to the photodetachment from the ground state  $\text{NH}_4^-$  to its neutral ground  $\text{NH}_4$  ( $3\text{s } ^2\text{A}_1$ ). Both the anionic and neutral ammonia radicals have similar tetrahedral molecular geometries, which undergo barely any change during the photodetachment process, resulting in peak a appearing as a sharp atomic line. The binding energy of this vertical transition is the electron affinity of  $\text{NH}_4$ , determined to be  $3833(43)\text{ cm}^{-1}$  or  $0.475(5)\text{ eV}$ , consistent with the previous experimental findings by the Continetti group ( $0.48 \pm 0.06\text{ eV}$ )<sup>8</sup> and the Bowen group ( $0.48\text{ eV}$ ),<sup>11</sup> as well as with the newest theoretical result by Ortiz group ( $0.477\text{ eV}$ ).<sup>18</sup> Peak c, with a measured binding energy of  $9079(578)\text{ cm}^{-1}$  or  $1.12(7)\text{ eV}$ , is associated with the  $\text{H}^-(\text{NH}_3)$  complex. This measured value is also in close agreement with the predicted value by the Ortiz group ( $1.079\text{ eV}$ )<sup>18</sup> and the experimental value by the Bowen group ( $1.11 \pm 0.01\text{ eV}$ ).<sup>11</sup> Considering that the equilibrium geometry of  $\text{H}^-(\text{NH}_3)$  corresponds to the pure repulsive region of its neutral PES, peak c appears broad and structureless due to the rapid dissociation dynamics. The weak peak b exhibits photon-energy dependence, observed at 460 and 515 nm but not at

**Figure 1.** Full cryo-SEVI spectra of  $\text{NH}_4^-$  and  $\text{H}^-(\text{NH}_3)$ . The photoelectron image is obtained at 460 nm. The double-headed arrow indicates the polarization of the detachment laser. Peaks d–g are observed for the first time in the current work.

700 nm, as shown in Figure 2a. This observation is consistent with that observed by the Bowen group at 488 nm<sup>11</sup> but the Continetti group did not observe it at 775 nm.<sup>8</sup> This phenomenon might be due to a shape resonance during the photodetachment, analogous to observations in  $\text{Na}^-$ <sup>35</sup> and  $\text{Cs}^-$ .<sup>36</sup> Peak b arises from excitation of a vibrational mode during the resonant photodetachment, with a determined binding energy of  $6743(728)\text{ cm}^{-1}$  or  $0.84(9)\text{ eV}$ . The energy difference between peak b and peak a is  $2910(729)\text{ cm}^{-1}$ , closely matching the calculated vibrational frequency of the symmetric stretching mode of  $\text{NH}_4$  by the Ortiz group ( $3109\text{ cm}^{-1}$ )<sup>37</sup> and the Guo group ( $3032\text{ cm}^{-1}$ ).<sup>12</sup> Thus, the final state of peak b is assigned to the symmetric stretching vibration mode ( $\nu_1, \text{A}_1$ ) of neutral  $\text{NH}_4$ .

A series of sharp peaks labeled as d–g appear in the photoelectron spectra at higher photon energies, which have not been observed before. During the experiment, we found that the relative intensity of peak c to other peaks changed when varying the trap time, as shown in Figure 2b. To determine which anionic isomer peaks d–g belong to, the relative intensity ratio of each peak at 45 ms to 5 ms is plotted in the Figure 2c. All spectra are normalized using peak a to compensate for the fluctuation of the ion beam intensity. For peaks from the same initial state of anions, their relative intensity should change uniformly versus the storage time in the ion trap.<sup>28,38</sup> Since the relative ratios of peaks b and d–g are consistent with that of peak a at 460 nm and peaks f–g are consistent with peak d at 440 nm, peaks a, b, and d–g are all from the same anionic ground state of  $\text{NH}_4^-$ . The energy difference between peaks a and d is measured to be  $15052(94)\text{ cm}^{-1}$ , or  $1.866(12)\text{ eV}$ , which is in excellent agreement with the principal Schüler band ( $15061.61\text{ cm}^{-1}$ ,  $^2\text{T}_2$  ( $3\text{p}$ )  $\rightarrow$   $^2\text{A}_1$  ( $3\text{s}$ ) of neutral  $\text{NH}_4$ ).<sup>21</sup> This indicates that peak d corresponds to the transition from the ground state of  $\text{NH}_4^-$  DRA to the first electronically excited state of  $\text{NH}_4$ . The theoretical result  $1.749\text{ eV}$  by Ortiz et al.<sup>25</sup> also supports this identification. Another evidence is the distinct anisotropy parameter ( $\beta$ ) of the photoelectron angular distribution (PAD), as the image in Figure 1 displays.  $\beta$  is 1.74 for peak a while it is  $-0.42$  for peak d at the wavelength 460 nm. For  $\text{NH}_4^-$ , the outermost electron occupies the diffuse  $2\text{a}_1$  orbital, similar to the  $3\text{s}$  orbital of  $\text{Na}^-$ .

**Figure 2.** a) Photoelectron spectra of  $\text{NH}_4^-$  and  $\text{H}^-(\text{NH}_3)$  acquired at various photon energies. b) Comparison of photoelectron spectra obtained with the storage time 5 ms (blue) and 45 ms (black) in the cryogenic ion trap at 460 nm. c) Relative intensity ratio of each peak with a storage time of 45 ms to 5 ms. The spectra were normalized using peak a. The black squares indicate peaks a–f obtained at 460 nm, and the blue circles indicate peaks d, f, and g obtained at 440 nm.

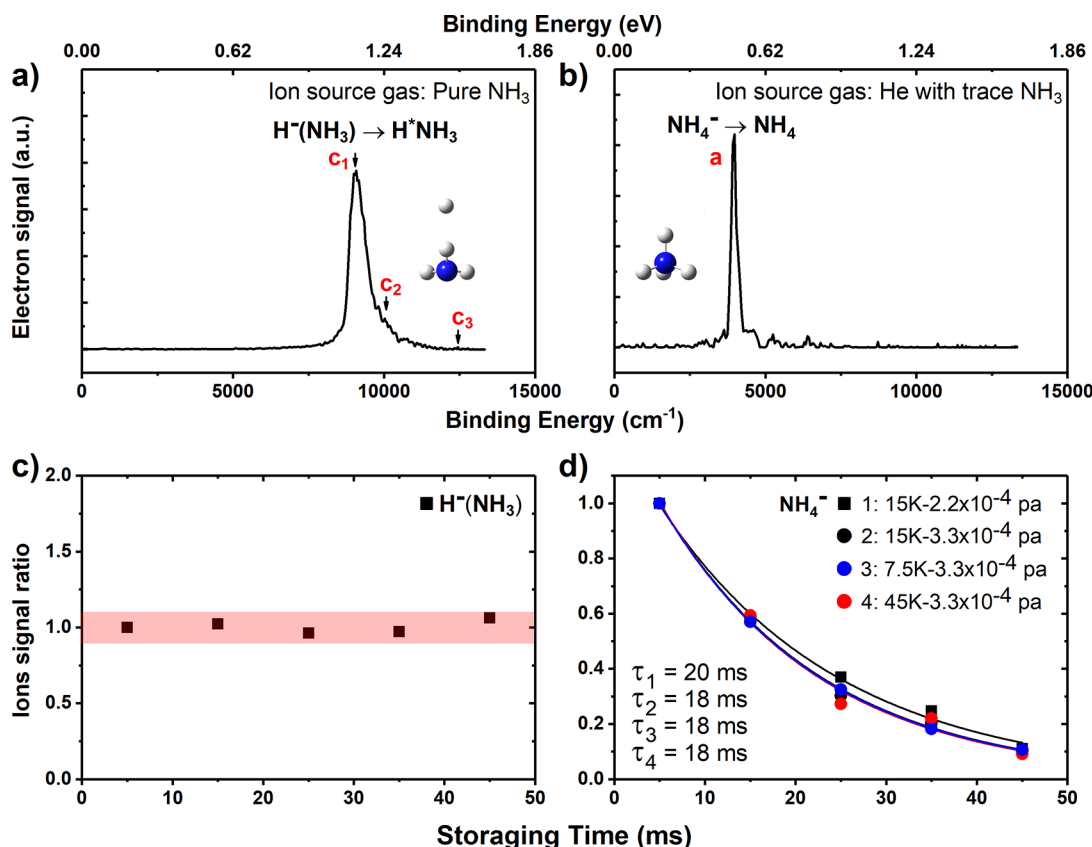

Consequently, the detached electrons associated with peak a are expected to exhibit a p-wave and have a positive  $\beta$  value, whereas those related to peak d are anticipated to have a different value owing to the two-electron process: one 3s electron is photodetached with another 3s electron excited to 3p. Therefore, the outgoing photoelectron for peak d cannot be the p-wave.<sup>39</sup> Since the next Rydberg excited state ( $3d\ ^2T_2$ ) of  $\text{NH}_4$  is  $21514\text{ cm}^{-1}$  higher than its ground state,<sup>25</sup> peaks e–g are impossible from other Rydberg states. Instead, they are assigned to three vibrational modes of  $\text{NH}_4$  in its excited state  $3p\ ^2T_2$ . The high-level calculation of the vibrational frequencies of  $\text{NH}_4$  in its Rydberg excited state  $3p\ ^2T_2$  is a nontrivial task. Since Rydberg  $\text{NH}_4$  ( $3p\ ^2T_2$ ) has a compact core  $\text{NH}_4^+$  and its vibrational frequencies would be similar to those of  $\text{NH}_4^+$ , we estimated them using the vibrational frequencies of  $\text{NH}_4^+$ . The vibrational frequencies are measured to be  $1353(182)$ ,  $2185(142)$ , and  $3355(196)\text{ cm}^{-1}$ , respectively, according to the gap among peaks d–g. They are close to the calculated values for the umbrella mode ( $\nu_4$ ,  $T_2$ ,  $1494\text{ cm}^{-1}$ ), the twisting mode ( $\nu_2$ , E,  $1740\text{ cm}^{-1}$ ), and the stretching mode ( $\nu_3$ ,  $T_2$ ,  $3500\text{ cm}^{-1}$ ) of  $\text{NH}_4^+$  at the B2PLYPD3/aug-cc-pVTZ level. The binding energies of all observed peaks, including assignments and  $\beta$  values of PADs, are listed in Table 1.

To explain the different changing trends observed for two isomers in the cryogenic ion trap, we further conducted the experiment under varying conditions. Theoretical predictions suggest two possible reactions in the ion trap.<sup>8,40</sup> One involves the conversion from  $\text{NH}_4^-$  DRA to  $\text{H}^-(\text{NH}_3)$  complex, while the other entails the dissociation of  $\text{NH}_4^-$  into  $\text{H}^-$  and  $\text{NH}_3$ . By carefully controlling the ion source parameters, we can

**Table 1.** Binding Energy, Anisotropy Parameter ( $\beta$ ) of the Photoelectron Angular Distribution (PAD), Assignment of Observed Peaks, and Experimental/Theoretical Vibrational Frequencies of the Neutral  $\text{NH}_4$

Peak	Binding Energy ( $\text{cm}^{-1}$ ) <sup>a</sup>	$\beta$	Assignment	Vibrational Frequency ( $\text{cm}^{-1}$ ) Experimental/Theoretical <sup>b</sup>
a	3833(43)	1.74	$\text{NH}_4^- \rightarrow \text{NH}_4$ ( $3s\ ^2A_1$ )	
b	6743(728)	1.06	$\text{NH}_4^- \rightarrow (\nu_1, A_1)$ of $\text{NH}_4$ ( $3s\ ^2A_1$ )	2910/3032
c	9079(578)	1.33	$\text{H}^-(\text{NH}_3) \rightarrow \text{H}^*\text{NH}_3$	
d	18885(84)	−0.42	$\text{NH}_4^- \rightarrow \text{NH}_4$ ( $3p\ ^2T_2$ )	
e	20238(161)	−0.42	$\text{NH}_4^- \rightarrow (\nu_4, T_2)$ of $\text{NH}_4$ ( $3p\ ^2T_2$ )	1353/1494
f	21070(115)	−0.14	$\text{NH}_4^- \rightarrow (\nu_2, E)$ of $\text{NH}_4$ ( $3p\ ^2T_2$ )	2185/1740
g	22240(177)	0.03	$\text{NH}_4^- \rightarrow (\nu_3, T_2)$ of $\text{NH}_4$ ( $3p\ ^2T_2$ )	3355/3500

<sup>a</sup>The value in the parentheses is the full width at the half-maximum (fwhm) of each peak. <sup>b</sup>The experimental results were obtained according to the energy gaps among the observed peaks. The theoretical value  $\nu_1 = 3032\text{ cm}^{-1}$  for the ground  $\text{NH}_4$  ( $3s\ ^2A_1$ ) is from ref 12, while the other values for the excited  $\text{NH}_4$  ( $3p\ ^2T_2$ ) are calculated results in the present work.

**Figure 3.** Photoelectron spectra of pure a)  $\text{H}^-(\text{NH}_3)$  and b)  $\text{NH}_4^-$  at 750 nm. The black curve in panel a is in excellent agreement with the raw theoretical spectrum from ref 8. Tags  $\text{C}_1$ – $\text{C}_3$  denote the three predicted structures of  $\text{H}^-(\text{NH}_3)$ .<sup>8</sup> The geometric structures of  $\text{H}^-(\text{NH}_3)$  and  $\text{NH}_4^-$  are depicted in each panel. c) Ion signal of  $\text{H}^-(\text{NH}_3)$  as a function of the storage time in the ion trap. d) The ion signal of  $\text{NH}_4^-$  as a function of the storage time in the ion trap at different pressures and temperatures of the ion trap. The tunneling lifetime of  $\text{NH}_4^-$  was obtained via exponential fitting  $I(t) = I_0 e^{-t/\tau}$ . The obtained values of  $\tau$  are listed in the lower left corner.

generate pure  $\text{H}^-(\text{NH}_3)$  and  $\text{NH}_4^-$  separately. When utilizing pure ammonia gas, only  $\text{H}^-(\text{NH}_3)$  was produced, while a weaker signal of pure  $\text{NH}_4^-$  can be observed when using trace ammonia carried by helium, as shown in Figure 3a,b. Grumblin and Sanov<sup>41</sup> also acquired photoelectron spectra of  $\text{H}^-(\text{NH}_3)$  alone using pure ammonia as the ion source gas. The pure  $\text{NH}_4^-$  alone has not been previously reported. The fact that these two anionic isomers could exist independently implies that  $\text{NH}_4^-$  DRA does not undergo transformation into the  $\text{H}^-(\text{NH}_3)$  complex in the cryogenic ion trap.

The only remaining possible reaction pathway in the cryogenic ion trap is the dissociation of  $\text{NH}_4^-$  DRA. Following the confirmation that only  $\text{H}^-(\text{NH}_3)$  exists in the cryogenic ion trap via the energy spectrum (Figure 3a), the ion intensity was recorded as the storage time ranged from 5 to 45 ms. As illustrated in Figure 3c, there is no observable change in the intensity of  $\text{H}^-(\text{NH}_3)$ . Furthermore, Figure 3a shows the high-resolution spectra of the  $\text{H}^-(\text{NH}_3)$  complex, demonstrating excellent agreement with the high-level quantum dynamic simulations conducted by Hu et al.<sup>8</sup> Similarly, subsequent to confirming the exclusive presence of  $\text{NH}_4^-$  in the cryogenic ion trap based on the energy spectrum (Figure 3b), we observed an exponential decrease in the ion intensity of  $\text{NH}_4^-$  relative to the storage time, as shown in Figure 3d. To evaluate the possible collision or reaction effects caused by buffer gas (80% He + 20%  $\text{H}_2$ ) in the ion trap, we varied the density of the buffer gas and the temperature of the ion trap. However, no notable change in the decay trend was observed, as shown in

Figure 3d. The tunneling lifetime  $\tau$  of  $\text{NH}_4^-$  into  $\text{H}^-$  and  $\text{NH}_3$  was determined through exponential fitting to  $I(t) = I_0 e^{-t/\tau}$ , where  $I$  represents the intensity of  $\text{NH}_4^-$  and  $t$  denotes the storage time of  $\text{NH}_4^-$  in the ion trap. The statistical average value of  $\tau$  was found to be 19(2) ms. Notably, the tunneling lifetime of  $\text{NH}_4^-$  is much longer than that of the neutral  $\text{NH}_4$ .<sup>8</sup> To better understand this observation, we calculated the potential energy curve of  $\text{NH}_4^-$  dissociated into  $\text{H}^-$  and  $\text{NH}_3$  along the  $\text{C}_{3v}$  pathway at the B2PLYPD3/aug-cc-pVTZ level, as shown in Figure 4. The barrier on the dissociation path is calculated as 1.09 eV relative to the energy of  $\text{NH}_4^-$  at equilibrium without the zero-energy correction, which is consistent with the previous theoretical results by Cardy et al. (0.8 eV),<sup>42</sup> Matsunaga et al. (1.4 eV),<sup>17</sup> and Melin et al. (0.7 eV).<sup>43</sup>

In conclusion, employing the cryo-SEVI method, we obtained high-resolution photoelectron spectra of double Rydberg anion  $\text{NH}_4^-$  and ion-complex  $\text{H}^-(\text{NH}_3)$ . The observed spectra exhibit excellent agreement with the previous quantum dynamics calculations. Additionally, several new peaks were observed, providing a solid support for assigning the Schüler band to the transition from the  $^2\text{T}_2$  (3p)  $\rightarrow$   $^2\text{A}_1$  (3s) of Rydberg radical  $\text{NH}_4$ . Furthermore, we observed the tunneling dissociation of  $\text{NH}_4^-$  in the cryogenic ion trap, estimating its lifetime as 19(2) ms. The study contributes to a deeper understanding of the exotic  $\text{NH}_4$  and the reaction dynamics of  $\text{H} + \text{NH}_3 \rightarrow \text{H}_2 + \text{NH}_2$ .

**Figure 4.** Calculated energy curve of dissociation of  $\text{NH}_4^- \rightarrow \text{H}^- + \text{NH}_3$  along the  $C_{3v}$  dissociation pathway. The tunneling process is schematically represented by the red curve.  $d$  is the distance between the N and H atoms, as illustrated in the inset.  $\text{NH}_4^-$  at equilibrium is considered the reference point for energy. The asymptotic energy of  $\text{H}^-$  and  $\text{NH}_3$  radicals is 0.4 eV lower than that of  $\text{NH}_4^-$ .<sup>8</sup>
